Exploring the Limits of Super-Planckian Far-Field Radiative Heat Transfer Using 2D Materials

Víctor Fernández-Hurtado, João I. Fernández-Domínguez, Johannes Feist, Francisco J. García-Vidal, and Juan Carlos Cuevas

ABSTRACT: Very recently it has been predicted that the far-field radiative heat transfer between two macroscopic systems can largely overcome the limit set by Planck’s law if one of their dimensions becomes much smaller than the thermal wavelength ($\lambda_{Th} \approx 10 \mu m$ at room temperature). To explore the ultimate limit of the far-field violation of Planck’s law, here we present a theoretical study of the radiative heat transfer between two-dimensional (2D) materials. We show that the far-field thermal radiation exchanged by two coplanar systems with a one-atom-thick geometrical cross section can be more than 7 orders of magnitude larger than the theoretical limit set by Planck’s law for blackbodies and can be comparable to the heat transfer of two parallel sheets at the same distance. In particular, we illustrate this phenomenon with different materials such as graphene, where the radiation can also be tuned by an external gate, and single-layer black phosphorus. In both cases the far-field radiative heat transfer is dominated by TE-polarized guiding modes, and surface plasmons play no role. Our predictions provide a new insight into the thermal radiation exchange mechanisms between 2D materials.

KEYWORDS: radiative heat transfer, 2D materials, super-Planckian, far-field, graphene, black phosphorus

Radiation is, together with convection and conduction, one of the three basic mechanisms of heat exchange between bodies. The maximum thermal energy that can be transferred between two objects via radiation is, in principle, set by Planck’s law for blackbodies, which assumes that both of them are perfect absorbers at all frequencies and that all dimensions involved in the problem are larger than $\lambda_{Th}$. However, it is known that when the separation between two bodies is smaller than $\lambda_{Th}$, the radiative heat transfer can be enhanced by orders of magnitude due to the contribution of evanescent waves. This phenomenon, known as near-field radiative heat transfer (NFRHT), has been confirmed in recent years by several experiments exploring different geometries, materials, and distances between the two objects, ranging from micrometers down to a few nanometers. On the other hand, Planck’s law is also expected to fail when objects have dimensions smaller than $\lambda_{Th}$, even in the far field. In this case, nothing prevents, in principle, overcoming the Planckian limit. In fact, it has been predicted that the far-field thermal emission of a single object can be super-Planckian, but in practice this is very difficult to achieve, and this phenomenon has never been observed. In the context of radiative heat transfer, which is the problem that we are interested in, only very recently have we predicted that the Planckian limit can also be largely surpassed in the far-field regime, i.e., when the separation of the objects is larger than $\lambda_{Th}$. In particular, we have shown theoretically that the far-field radiative heat transfer (FFRHT) between micrometer-size devices can overcome the blackbody limit by several orders of magnitude if their thickness is much smaller than $\lambda_{Th}$. Moreover, we have shown that the enhancement over Planck’s law increases monotonically as the device thickness is reduced, which leads us to the fundamental question on the limits of super-Planckian FFRHT. The goal of this work is to explore this issue with the help of 2D materials, i.e., with materials with a one-atom-thick geometrical cross section, which constitutes the ultimate limit of thin systems.

2D materials have been extensively studied in recent years in the context of radiative heat transfer. In particular, several works have taken advantage of the near-field density of photonic states in these systems to modify the characteristics of emitters in a wide variety of scenarios. Most of the theoretical work in the case of graphene has focused on the possibility to tune and enhance the NFRHT mediated by the surface plasmon–polaritons sustained by this material. For instance, it has been predicted that the NFRHT between polar...
dielectrics can be boosted by placing a graphene layer on top. Other studies have proposed periodic graphene ribbon arrays to induce hyperbolic modes and thus further enhance the \( \text{NFRHT} \) between 2D systems. The \( \text{NFRHT} \) between graphene nanodisks has also been studied, and the analysis of the time scales of radiative heat transfer in this setup suggests that this process is ultrafast. Let us also mention that the near-field thermal conductance between Dirac 2D materials scales as the inverse of the distance between two flakes. However, and despite all these recent advances, \( \text{FFRHT} \) between 2D materials remains unexplored. As explained above, 2D materials constitute ideal systems in which one can explore the ultimate limit of the violation of Planck’s law in the far-field regime. Moreover, from an applied viewpoint, understanding the absorption and emission of radiation in 2D materials is key to properly characterize their thermal properties and harness their unique mechanical and electronic features. For these reasons, we present in this work a theoretical study of the \( \text{FFRHT} \) between systems with a one-atom-thick geometrical cross section. In particular, we demonstrate that the \( \text{FFRHT} \) between sheets of 2D materials like graphene or single-layer black phosphorus can overcome the Planckian limit by more than \( 7 \) orders of magnitude. Moreover, we show that, contrary to the known \( \text{NFRHT} \) mechanism, surface plasmon–polaritons play no role in this case, and this remarkable heat transfer is instead dominated by TE-polarized guiding modes.

**RESULTS AND DISCUSSION**

Let us start by analyzing the \( \text{FFRHT} \) between two coplanar graphene sheets. This system is schematically represented in Figure 1a. In this case, two identical graphene sheets at temperatures \( T_1 \) and \( T_2 \) (\( T_1 < T_2 \)) are separated by a gap \( d \). The length of the flakes is denoted by \( L_x \), and, for simplicity, we shall assume that they are infinitely wide in the \( x \)-direction (\( L_x \to \infty \)). Notice that, as shown in Figure 1a, both flakes are coplanar, and thus, for the radiative problem they constitute systems with a one-atom-thick geometrical cross section. In order to compute the power exchanged in the form of thermal radiation between these 2D systems, we make use of the theory of fluctuational electrodynamics. In this theory, the material properties enter via the dielectric function, which in the graphene case can be determined from the electrical conductivity. The 2D conductivity of graphene, \( \sigma_{2D} \), is calculated within the random phase approximation can be expressed in terms of the chemical potential (\( \mu \)), temperature (\( T \)), and scattering energy (\( E_s \)).

\[
\sigma_{2D} = \sigma_{\text{intra}} + \sigma_{\text{inter}}
\]

where the intraband and the interband contributions are given by

\[
\sigma_{\text{intra}} = \frac{2e^2}{\hbar \pi (\Omega + iy)} \ln \left[ 2 \cosh \left( \frac{1}{2t} \right) \right]
\]

\[
\sigma_{\text{inter}} = \frac{e^2}{4\hbar} \left[ \frac{1}{2} + \frac{1}{\pi} \arctan \left( \frac{\Omega - 2t}{2t} \right) \right] - i \frac{\ln \left( (\Omega + 2t)^2 + (2t)^2 \right)}{2\pi}
\]

with \( \Omega = \hbar \omega / \mu \), \( \gamma = E_s / \mu \), and \( t = k_B T / \mu \). In Figure 1b, we show the normalized 2D conductivity of graphene, in units of \( \sigma_0 = e^2 / 2\pi \hbar \), for \( T = 300 \) K, \( E_s = 10^{-3} \) eV, and different values of the chemical potential. As one can see, graphene resembles a Drude metal in the infrared regime whose metallic character increases with the chemical potential. Let us remark that the value chosen in this case for \( E_s \) corresponds to a graphene sheet with a very large relaxation time, \( \tau = \hbar / E_s \), which is normally the desired scenario in the field of graphene plasmonics. We will show below that the opposite limit is indeed more favorable for the absorption and emission of radiation between 2D materials.

In order to calculate the \( \text{FFRHT} \), we make use of a result derived in a recent work \(^3\) with the help of a thermal discrete dipole approximation. \(^2\) This result establishes a connection between the \( \text{FFRHT} \) between two objects and their absorption efficiencies, i.e., their absorption cross sections divided by their geometrical cross sections. Assuming that a sheet of a 2D material can be modeled as a parallelepiped (see below), this result indicates that the radiative power exchanged between two identical flakes at temperatures \( T_1 \) and \( T_2 \) separated by a gap \( d \) much larger than both \( \lambda_{\text{TH}} \) and their characteristic dimensions is given by

\[
P = \frac{\pi}{2} AF_{12} \int_0^\infty \left[ Q_{12}(\omega) + Q_{12M}(\omega) \right]\left[ I_{\text{BB}}(\omega, T_1) - I_{\text{BB}}(\omega, T_2) \right] d\omega
\]

where \( A \) is the geometrical cross section of the bodies and \( F_{12} = \delta / 2d \) is the geometrical view factor, \(^7\) where \( \delta \) is the geometric thickness of the 2D material. On the other hand, \( Q_{12M}(\omega) \) is the frequency-dependent absorption efficiency for a plane wave with normal incidence and transverse magnetic (TM) or
Figure 2. (a) Spectral thermal conductance as a function of the radiation frequency for a system composed of two graphene flakes of length $L_z = 10 \mu m$, $E_z = 10^{-4}$ eV, and a gap $d = 1$ mm (see upper inset). The different lines correspond to distinct chemical potentials (see legend in (b)), and the temperature is 300 K. The lower inset shows the corresponding absorption efficiency $Q_{\text{TE}}(\omega)$ in the same frequency range as the spectral conductance. (b) Total thermal conductance $G_{\text{th}}$, normalized by the blackbody results, for the same system as in panel (a) and plotted as a function of $L_z$ for different chemical potentials. The dashed orange line is proportional to $L_z^2$. The vertical dotted line indicates approximately the length at which the conductance for $\mu = 0.5$ eV starts to saturate (see text). Let us stress that these normalized results do not depend on the gap as long as $d$ is much larger than the thermal wavelength.

transverse electric (TE) polarization, and $I_{\text{BB}}(\omega, T)$ is the Planck distribution function, which is given by

$$I_{\text{BB}}(\omega, T) = \frac{\omega^2}{4\pi^2 c^2} \frac{\hbar \omega}{\exp(\hbar \omega/k_b T) - 1}$$

(4)

where $c$ is the speed of light. The blackbody limit can be obtained by assuming that the absorption efficiencies $Q_{\text{TM,TE}}(\omega) = 1$ for all frequencies. In this case, eq 3 reduces to the Stefan–Boltzmann law: $P_{\text{BB}} = \sigma A F_{\text{th}}(T^4 - T_f^4)$, where $\sigma = 5.67 \times 10^{-8}$ W/(m$^2$ K$^4$). It is worth mentioning that we have verified the validity of eq 3 to calculate the FFRHT between 2D materials by comparing its results with numerically exact simulations within the framework of fluctuational electrodynamics (Supporting Information, Figure S1).

According to eq 3, $Q_{\text{TM,TE}}(\omega)$ are required to calculate the FFRHT between two graphene sheets. Since our system is one atom thick in the $y$-direction (Figure 1a), a wave impinging with the electric field pointing in the $y$-direction does not generate any current in that direction. Hence, the absorption cross section of TM plane waves vanishes ($Q_{\text{TM}}(\omega) = 0$), and only $Q_{\text{TE}}(\omega)$ contributes to the FFRHT. Note that free-space propagating waves cannot couple efficiently to surface plasmons in graphene, which lie far outside the light line, due to the large mismatch in in-plane momentum. We have calculated this efficiency using COMSOL MULTIPHYSICS, where we have modeled our system as a 3D parallelepiped with an effective dielectric constant$^{43}$ (see Supporting Information). In accordance with experimental evidence, we have taken $\delta_{\text{graphene}} = 0.37$ nm for the thickness of a graphene monolayer.$^{43}$

Figure 1c shows $Q_{\text{TE}}(\omega)$ as a function of the radiation frequency $\omega$ (solid lines) for different chemical potentials and for a scattering energy $E_z = 10^{-4}$ eV. Notice that the absorption cross section is much larger than the geometrical one in the infrared frequency range, which shows that graphene is a very efficient broadband infrared absorber, even when the incident vector of the plane wave is parallel to the graphene sheet (see inset in Figure 1c). Notice also that $Q_{\text{TE}}(\omega)$ increases for decreasing frequency, which is due to the increase of losses in the system (see Figure 1b).

In order to get further insight into the remarkable radiation absorption of a graphene flake, we have derived an analytical expression for $Q_{\text{TE}}(\omega)$ in eq 3 as follows. The radiation absorption can be understood as a two-step process. First, a TE plane wave impinges in the graphene flake (see inset in Figure 1c) and couples to the guiding modes of our system. Second, these modes propagate along the $z$-direction, while being progressively absorbed by the graphene flake. Taking both processes into account (Supporting Information, Figure S2), the frequency-dependent absorption efficiency can be expressed as

$$Q_{\text{TE}}^m(\omega) = 1 - \frac{e^{-2\delta\Im{k}_{z}}}{\delta\Im{k}_{z}}$$

(5)

Here, $k_z$ corresponds to the $z$-component of the graphene mode wave vector and $k_z$ represents the $y$-component of the same wave vector in a vacuum. In eq 5, the factor $1/\delta\Im{k}_{z}$ is related to the coupling between the plane wave and the EM modes of the system, while the numerator $(1 - e^{-2\delta\Im{k}_{z}})$ accounts for the absorption of the guiding wave along the graphene sheet. We have computed the dispersion relation of the leaky guided modes of our system by using standard dielectric waveguide theory$^{44}$ (see Supporting Information). In Figure 1c we show the analytical results for the absorption efficiency $Q_{\text{TE}}^m(\omega)$ (dashed lines), and, as one can see, there is an excellent agreement with the exact numerical simulations. This agreement allows us to conclude that the extraordinary absorption efficiency of a graphene flake in this configuration is due to the fact that it behaves as a lossy waveguide that absorbs the radiation via the excitation of guided TE modes. In particular, because of the low impedance mismatch, the incident radiation is efficiently coupled into guided modes and is eventually absorbed.

Once $Q_{\text{TE}}(\omega)$ is known, we can use eq 3 to calculate the FFRHT between two graphene flakes in the coplanar configuration (see Figure 1a). We shall characterize the FFRHT in terms of the room-temperature linear heat conductance per unit of length, $G_{\text{th}} = P/(L \Delta T)$, in the limit $\Delta T = (T_z - T_f) \rightarrow 0$. Figure 2a shows the spectral $G_{\text{th}}$, i.e., the conductance per unit of frequency, for two graphene sheets of length $L_z = 10 \mu m$, $E_z = 10^{-4}$ eV, and a gap $d = 1$ mm. It can be observed that the system exhibits a broadband FFRHT spectrum, similar to the FFRHT between metals.$^5$ The conductance peak appears at $\omega = 9 \times 10^{10}$ rad/s for all chemical potentials. This maximum originates from the
calculated for the frequency at which the spectral conductance reaches its maximum ($\omega = 1.2 \times 10^{11}$ rad/s).

We have shown that the FFRHT between graphene sheets can overcome the Planckian limit by more than 4 orders of magnitude. However, our analysis also suggests that the thermal conductance could be further enhanced by increasing the intrinsic losses in the graphene sheets. To test this idea, we have calculated the FFRHT for these graphene sheets assuming a larger value for the scattering energy $E_s$. Figure 3a shows the normalized 2D conductivity of graphene for $E_s = 0.01$ eV, i.e., 2 orders of magnitude larger than in the examples above. The corresponding results for the absorption efficiency $Q_{\text{TE}}(\omega)$ are displayed in Figure 3b. The absorption cross section is again orders of magnitude larger than the geometrical one, and, more importantly, it is also higher than in the previous case. Figure 3c shows the spectral $G_{\text{th}}$ for $L_z = 10 \mu m, E_s = 0.01$ eV, and a gap $d = 1$ mm. In this case the maximum of the spectral $G_{\text{th}}$ is strongly blue-shifted ($\omega = 1.3 \times 10^{13}$ rad/s), and the relevant frequencies for the FFRHT are also higher. The reason for this blue-shift is that $Q_{\text{TE}}(\omega)$ adopts larger values at frequencies that have a better overlap with Planck distribution function at room temperature. As a consequence, the total thermal conductance $G_{\text{th}}$ is much higher in this case, as we illustrate in Figure 3d. Notice that in this case the Planckian limit can be overcome by more than 7 orders of magnitude. Thus, we see here that the graphene with a high density of impurities (i.e., with low mobility), which is normally dismissed for optoelectronic and plasmonic applications, is more efficient regarding thermal emission and absorption.

For the sake of comparison, we have also analyzed the FFRHT between two graphene sheets of the same dimensions as those of Figure 3c ($\mu = 0.3$ eV) now parallel to each other
and separated by a distance $d$ along the normal direction. In that case, the geometrical cross section is $27,000$ times larger than in the coplanar configuration and Planck’s law would thus predict $27,000^2$ higher heat transfer efficiency than in the coplanar case. However, the FFRHT between the graphene sheets in this case is only $4$ times larger, and it does not exhibit an enhancement over Planck’s law. Indeed, the ratio with the blackbody results is $1.5 \times 10^{-3}$. This confirms that the FFRHT between coplanar sheets is truly remarkable and that its absolute value is comparable with other setups that have a much higher geometrical cross section. Moreover, we have performed additional simulations to verify if such FFRHT could be measured in a realistic experimental setup. We have calculated the FFRHT between two graphene sheets with $L_x = 20 \ \mu m$, $L_y = 60 \ \mu m$, $\mu = 0.5 \ eV$, and $E_g = 0.01 \ eV$ and separated by a gap of $20 \ \mu m$, where the thermal radiation is already dominated by the far-field contribution. The dimensions chosen for both the graphene sheets and the gap are within reach of state-of-the-art calorimetric techniques. \textsuperscript{45,46} In order to compute the FFRHT, we have made use of the code SCUFF-EM, which implements a fluctuating-surface-current approach to the radiative heat transfer problem and provides numerically exact results within the framework of fluctuational electrodynamics. \textsuperscript{45,46} The room-temperature linear heat conductance between the flakes is in this case $1.62 \ \text{pW/K}$, which is within the sensitivity of existent calorimetric techniques. \textsuperscript{45,46}

At this point one may wonder whether the dramatic violation of Planck’s law discussed above for the case of graphene may also occur in other 2D materials. To show that this is actually the case, we now turn to analyze the case of single-layer black phosphorus (SLBP). We have computed the FFRHT between two coplanar SLBP sheets (see Figure 1a). The distinctive steps of the atomic structure of SLBP are in our case placed along the $z$ direction. We have modeled the dielectric properties of a black phosphorus monolayer in an analogous way to graphene, and its 2D conductivity has been taken from previous studies. \textsuperscript{49} Both the real (solid line) and the imaginary (dashed line) part of the normalized conductivity of single-layer black phosphorus for $T = 300 \ K$ and $E_g = 0.01 \ eV$, for two different dopings ($n$). (b) Frequency-dependent absorption efficiency for a plane wave with transverse electric polarization ($Q_{TE}(\omega)$) and normal incidence into an SLBP sheet with length $L_x = 10 \ \mu m$ and infinite width (see inset). The solid lines correspond to the exact numerical results, while the dashed lines were obtained with eq 5. (c) Spectral $G_{th}$ as a function of $\omega$ for a system composed of two SLBP flakes of length $L_x = 10 \ \mu m$ separated by a gap $d = 1 \ mm$ (see inset). (d) Thermal conductance $G_{th}$ normalized by the blackbody results, for the same system as in panel (c) and plotted as a function of $L_{yz}$ for two different dopings. The dashed orange line is proportional to $L_{yz}^2$. The room-temperature linear conductance between the flakes is in this case $1.62 \ \text{pW/K}$, which is within the sensitivity of existent calorimetric techniques. \textsuperscript{45,46}
extraordinary absorption efficiency makes the FFRHT between flakes of these materials more than 7 orders of magnitude larger than the limit set by Planck’s law, which constitutes the ultimate violation of this law in the far-field regime. Finally, we have shown that the novel mechanism responsible for this FFRHT involves the propagation properties of TE-polarized guiding modes in these materials, modes that are usually irrelevant in the context of plasmonic or optoelectronic applications.
